ABSTRACT

This project presents the design, implementation, and evaluation of a Fruit Detection and Ripeness Analysis system using classical image processing techniques. The proposed system utilizes HSV (Hue, Saturation, Value) color space transformation, color thresholding, contour detection, and colour ratio analysis to detect fruits and estimate their ripeness from images. The system is capable of identifying multiple fruits, counting them, and classifying their ripeness levels as ripe, unripe, or semi-ripe based on color distribution.The preprocessing pipeline includes image resizing, noise reduction using Gaussian filtering, and conversion from BGR to HSV color space to enhance color-based segmentation. HSV thresholding is applied to isolate fruit regions, followed by morphological operations to remove noise and improve detection accuracy. Contour detection is used to identify individual fruits, and bounding boxes are drawn around detected objects.For each detected fruit, the system computes the percentage of red, green, and yellow pixels using color masking techniques. Based on these colour ratios, a ripeness score is calculated using rule-based logic. Fruits with higher red or yellow dominance are classified as ripe, while those with higher green dominance are classified as unripe. This approach provides an efficient and interpretable method for ripeness estimation without requiring complex machine learning models.The system is implemented using Python with OpenCV and NumPy for image processing, and Streamlit for developing an interactive user interface. The application allows users to upload images and visualize detection results, including fruit count, bounding boxes, colour percentages, and ripeness classification.The proposed solution is lightweight, fast, and suitable for real-time applications on standard systems without GPU support. It demonstrates that traditional image processing techniques can effectively solve practical problems such as fruit quality assessment, with potential applications in agriculture, food processing, and automated grading systems.

1. INTRODUCTION

1.1 Background and Motivation

Fruit detection and ripeness analysis are important tasks in computer vision with applications in agriculture, food quality control, and automated grading systems. Accurate identification of fruits and their ripeness helps improve quality, reduce waste, and support efficient decision-making.In this domain, two approaches exist: advanced deep learning methods that offer high accuracy but require heavy computation, and classical image processing techniques that are lightweight, interpretable, and efficient. This project adopts a classical approach to develop a simple and real-time fruit analysis system.The system uses HSV (Hue, Saturation, Value) color space to detect fruits and analyze their color composition. Through color thresholding and contour detection, individual fruits are identified and localized. A colour ratio-based method is then used to calculate ripeness scores and classify fruits as ripe, unripe, or semi-ripe.Implemented using Python, OpenCV, and Streamlit, the system provides a fast and user-friendly solution that works on standard systems without GPU support. This makes it suitable for practical applications such as fruit grading and quality assessment.

1.2 Problem Statement

Automated fruit detection and ripeness analysis require a system that can accurately identify fruits in an image, count multiple objects, and determine their ripeness in a consistent and efficient manner. Traditional manual inspection methods are subjective, time-consuming, and prone to human error, especially when dealing with large quantities of fruits or varying lighting conditions. Classical image processing approaches for fruit analysis face several challenges: (1) variations in lighting and shadows can affect color consistency, making detection less reliable; (2) background noise and similar-colored objects may interfere with accurate fruit segmentation; and (3) distinguishing between different ripeness stages based solely on visual cues requires precise color analysis and robust threshold selection. Additionally, detecting multiple fruits in a single image while avoiding false detections adds to the complexity of the system. While deep learning methods can improve accuracy, they require large datasets, high computational resources, and GPU support, which may not be feasible for lightweight or real-time applications. Therefore, there is a need for a simple, efficient, and interpretable solution that can perform fruit detection and ripeness classification without relying on complex training processes. This project addresses the problem of designing and implementing a fruit detection and ripeness analysis system using classical image processing techniques. The system leverages HSV color thresholding, contour detection, and colour

ratio-based logic to detect multiple fruits, calculate their color composition, and classify their ripeness in real time on standard CPU-based systems.

1.3 Objectives

- To design a complete image preprocessing pipeline including resizing, Gaussian noise reduction, and HSV color space conversion tailored for fruit detection.
- To implement HSV-based color thresholding for segmenting fruit regions and isolating key colors such as red, green, and yellow.
- To apply contour detection techniques to identify and localize multiple fruits within an image and draw bounding boxes around them.
- To compute colour ratios by analyzing the percentage of red, green, and yellow pixels for each detected fruit.
- To develop a rule-based ripeness scoring mechanism to classify fruits as ripe, unripe, or semi-ripe based on color distribution.
- To integrate all processing steps into a single pipeline capable of handling static images and producing real-time analysis.
- To design and implement a user-friendly interface using Streamlit for uploading images and visualizing detection results.
- To evaluate the system performance based on detection accuracy, fruit count correctness, and ripeness classification.
- To package the complete project with source code and dependencies for deployment on standard CPU-based systems without requiring GPU support.

1.4 Scope of the Report

This project focuses on developing a fruit detection and ripeness analysis system using classical image processing techniques.The system processes images through preprocessing, HSVcolor thresholding, contour detection, and colour ratio analysis to detect fruits, count them, and classify their ripeness as ripe, unripe, or semi-ripe.It is implemented using Python,OpenCV,and Streamlit, and is designed to run on standard CPU-based systems without requiring GPU support or complex machine learning models.The system supports analysis of staticimages and provides visual outputs including bounding boxes, fruit count,and ripeness classify

2. LITERATURE REVIEW

2.1 Traditional Feature-Based Methods

Before deep learning, traditional image processing techniques were widely used for object detection based on features such as color, shape, and texture. In fruit analysis, color-based segmentation is especially important because ripeness is strongly indicated by color changes.The HSV (Hue, Saturation, Value) color space is commonly used instead of RGB, as it separates color information from brightness, making it more robust to lighting variations. Using HSV thresholding, specific colors like red, green, and yellow can be effectively extracted for fruit detection.Contour detection is used to identify object boundaries and localize fruits within the image. For classification, rule-based methods such as colour ratio analysis are applied to determine ripeness levels (ripe, unripe, or semi-ripe).These methods are simple, efficient, and suitable for real-time applications, especially on systems without high computational resources.

2.2 Color-Based Fruit Detection Techniques

Color-based detection techniques are widely used in fruit analysis, as color is a key indicator of ripeness. Many studies have shown that using appropriate color spaces improves segmentation accuracy compared to raw RGB images.The HSV (Hue, Saturation, Value) color space is commonly used for fruit detection because it separates color information from intensity, making it more robust to lighting variations. By applying thresholding in HSV space, specific color ranges such as red, green, and yellow can be effectively extracted to identify fruits and their maturity stages.In addition to color segmentation, morphological operations and contour detection are used to refine segmented regions and accurately locate fruits within an image. These methods help remove noise and improve boundary detection.

For ripeness analysis, colour ratio techniques are often applied, where the proportion of different color pixels is calculated. Based on these ratios, fruits can be classified into categories such as ripe, unripe, or semi-ripe using rule-based approaches.Overall, color-based techniques provide a simple, efficient, and interpretable solution for fruit detection and ripeness estimation, especially in applications where computational resources are limited.

2.3 Gap Identified

Existing fruit detection systems either rely on traditional image processing methods or advanced deep learning techniques. Classical approaches are simple and efficient but often struggle with variations in lighting, background noise, and accurate ripeness classification. On the other hand, deep learning methods provide higher accuracy but require large datasets, complex training, and high computational resources.

Most existing solutions focus either on fruit detection or classification, but not both together in a simple and lightweight system. Additionally, many methods lack interpretability and are difficult to deploy on systems without GPU support.

This project addresses these gaps by developing a unified system that combines fruit detection, counting, and ripeness analysis using HSV-based color segmentation and rule-based classification. The proposed approach is efficient, interpretable, and suitable for real-time use on standard CPU-based systems.

3. DATASET DESCRIPTION

3.1 Fruits-360 Dataset

The Fruits-360 dataset is used as the primary data source for developing and evaluating the fruit detection and ripeness analysis system. It is a large-scale dataset containing thousands of labeled fruit images organized into multiple categories. The dataset is widely used in computer vision research for fruit classification and recognition tasks due to its high-quality images and structured organization.

Table 1: SAMPLE FRUIT CATEGORIES USED

Category Name	NUMBER OF IMAGES	USAGE
APPLE RED	600	RIPENESS ANALYSIS
APPLE GREEN	200	COLOR COMAPRSION
BANANA	400	TESTING
TOMATO	100	VALIDATION
ORGANGE	600	TESTING

Unlike large-scale real-world datasets, Fruits-360 provides clean and noise-free images, which makes it suitable for testing and validating classical image processing techniques. The dataset supports efficient experimentation and helps in understanding how color-based features contribute to fruit detection and ripeness classification.

3.2 Annotation Format and Patch Extraction

The Fruits-360 dataset is organized in a hierarchical folder structure, where each fruit category is stored in a separate directory. This structure allows easy access, loading, and processing of images for different fruit types.

The dataset typically contains two main sections:

- Training set
- Testing set

Within each section, images are grouped by fruit categories such as *Apple Red*, *Apple Green*, *Banana*, and others. Each folder contains multiple images of the same fruit type with slight variations in color, orientation, and size.

All images are captured under controlled conditions with a uniform background, which helps reduce noise and simplifies color-based segmentation. The file naming and directory structure make it convenient to iterate through images programmatically using libraries like OpenCV.

This organized structure supports efficient data handling and allows selective usage of specific fruit categories for analysis and experimentation.

All images are captured under controlled conditions with a uniform background, which helps reduce noise and simplifies color-based segmentation. The file naming and directory structure make it convenient to iterate through images programmatically using libraries like OpenCV.

This organized structure supports efficient data handling and allows selective usage of specific fruit categories for analysis and experimentation. In this project, selected fruit categories from the Fruits-360 dataset are used primarily for color analysis and testing the ripeness detection system. Images of fruits such as apples are chosen because they exhibit clear color changes during ripening stages.

The dataset is not used for training a machine learning model; instead, it is used to evaluate the effectiveness of classical image processing techniques such as HSV thresholding and contour detection. Sample images are processed to extract color features, detect fruit regions, and calculate colour ratios.

A subset of images is used for testing the system's ability to:

- Detect fruits accurately
- Count multiple fruits
- Classify ripeness based on color

This approach allows the system to be validated without the need for large-scale training, making it simple, efficient, and suitable for real-time applications.

3.3 Data Split

Table 2: Dataset Split Statistics

Split	Source	Proportion	Purpose
Train	Images from fruits-360 training folders	80%	HSV threshold
Test (held-out)	Images from fruits-360 testing folders	20% stratified	Validating fruit detection and detection and ripeness classification
SAMPLE IMAGES	Selected images from dataset	Few samples	Used for UI demonstration and output visualization

4. PREPROCESSING METHODOLOGY

Preprocessing is an important step in the system, as it prepares input images for accurate fruit detection and ripeness analysis. The applied techniques help improve image quality, reduce noise, and enhance color-based segmentation.

4.1 IMAGE RESIZING

Image resizing is performed to standardize the dimensions of all input images. This ensures consistent processing and reduces computational complexity. Large images are resized to a fixed resolution, which helps in faster execution while maintaining essential visual features required for detection.

4.2NOISE REMOVAL(GAUSSIAN BLUR)

Noise present in images can affect segmentation accuracy. To reduce this noise, Gaussian Blur is applied. This technique smooths the image by averaging pixel values with neighboring pixels, helping to remove small variations and unwanted details. As a result, object boundaries become clearer for further processing.

4.3 Color Space Conversion (BGR to HSV)

Images are converted from BGR (default OpenCV format) to HSV (Hue, Saturation, Value) color space. HSV is more suitable for color-based analysis because it separates color information (hue) from brightness (value). This makes the system more robust to lighting variations and improves the accuracy of color-based segmentation.

4.4 Image Masking

Image masking is used to isolate specific color regions in the image. Based on predefined HSV ranges, masks are created for colors such as red, green, and yellow. These masks highlight the fruit regions while suppressing the background, making it easier to detect objects of interest.

4.5 Morphological Operations

Morphological operations such as dilation and erosion are applied to improve the quality of the mask. These operations help remove small noise, fill gaps, and smooth object boundaries. As a result, the detected regions become more accurate and suitable for contour detection.

4.6 Visualization (Before vs After Processing)

To evaluate the effectiveness of preprocessing, both original and processed images are visualized. The comparison clearly shows improvements such as noise reduction, better segmentation, and clearer object boundaries. This step helps in validating the preprocessing pipeline and demonstrating its impact on detection performance.

Preprocessing Configuration	**Detection Accuracy**	**Ripeness Accuracy**	**Note**
Raw Image (No preprocessing)	~85%	~80%	No enhancement applied
+ Image Resizing	~87%	~82%	Standardized input size
+ Gaussian Blur	~89%	~85%	Noise reduced
+ HSV Conversion	~92%	~90%	Better color segmentation
+ Masking + Morphology	**Best (~95%)**	**Best (~93%)**	Final optimized pipeline

5. ALGORITHM: HSV Threshold + Colour Ratio + Ripeness Score

5.1 Algorithm Overview

The system implements a classical image processing pipeline for fruit detection and ripeness analysis. The approach consists of sequential stages including HSV color space conversion, color thresholding, contour-based fruit detection, colour ratio computation, and rule-based ripeness classification.Unlike deep learning models, this system does not require training. Instead, it uses predefined HSV ranges to segment fruit regions and applies mathematical logic to determine ripeness. The pipeline processes each input image and produces outputs such as bounding boxes, fruit count, color percentages, and ripeness labels.

5.2 Stage 1 — HSV Conversion

The input image is converted from BGR to HSV color space using OpenCV.

- HSV separates color (Hue) from brightness (Value)
- More robust to lighting variations compared to RGB

Formula Concept:

- Hue → color type
- Saturation → color intensity
- Value → brightness

This step prepares the image for accurate color-based segmentation.

5.3 Stage 2 — Color Thresholding (Red, Green, Yellow)

Color thresholding is applied to extract fruit regions based on HSV ranges.

- Red mask → identifies ripe regions
- Green mask → identifies unripe regions
- Yellow mask → identifies semi-ripe regions

Each mask is created using:

mask = cv2.inRange(hsv_image, lower_bound, upper_bound)

The output is a binary image where:

- White → detected color region
- Black → background

5.4 Stage 3 — Contour Detection (Fruit Detection)

Contours are extracted from the masked image using:

cv2.findContours()

Steps:

1. Detect object boundaries
2. Filter small noise using area threshold
3. Draw bounding boxes around detected fruits

Each contour corresponds to one fruit.

5.5 Stage 4 — Colour Ratio Calculation

For each detected fruit region:

- Count pixels of each color (Red, Green, Yellow)
- Calculate percentage:

  Red% = (Red pixels / Total pixels) × 100

  Green% = (Green pixels / Total pixels) × 100

  Yellow% = (Yellow pixels / Total pixels) × 100

These ratios represent the color composition of the fruit.

5.6 Stage 5 — Ripeness Score Computation

Ripeness is determined using rule-based logic:

- High Red/Yellow → Ripe
- High Green → Unripe
- Balanced → Semi-ripe

Example scoring:

Ripeness Score = (Red% × 0.6) + (Yellow% × 0.3) − (Green% × 0.2)

Classification:

- Score > Threshold → Ripe || Score < Threshold → Unripe

5.7 Stage 6 — Fruit Counting

The number of fruits is calculated based on detected contours:

Total Fruits = Number of valid contours

Each valid contour represents one fruit after filtering noise.

5.8 Complete Algorithm Flow

1. INPUT: Image (uploaded or dataset image)
2. PREPROCESSING: Resize → Gaussian Blur
3. HSV CONVERSION: Convert BGR → HSV
4. THRESHOLDING: Apply masks for Red, Green, Yellow
5. MORPHOLOGY: Clean mask (erosion + dilation)
6. CONTOUR DETECTION: Detect fruit regions
7. COLOUR ANALYSIS: Calculate color percentages
8. RIPENESS LOGIC: Compute score and classify
9. COUNTING: Count total fruits
10. OUTPUT: Display bounding boxes, labels, and results

TABLE:3 HSV Threshold Configuration

COLOR	HUE RANGE	PURPOSE
RED	0-10,160-180	DETECT RIPE FRUITS
GREEN	35-85	DETECT UNRIPE FRUITS
YELLOW	20-35	DETECT SEMI-RIPE FRUTIS

6. RESULTS AND ANALYSIS

6.1 Output Visualization

The system outputs are visualized using bounding boxes drawn around detected fruits along with labels indicating ripeness status. Each detected fruit is highlighted clearly, and additional information such as fruit count and ripeness score is displayed.

The visualization includes:

- Original image
- Processed (masked) image
- Final output with bounding boxes and labels

This helps in understanding how preprocessing and segmentation improve detection accuracy.

6.2 FRUIT DETECTION RESULTS

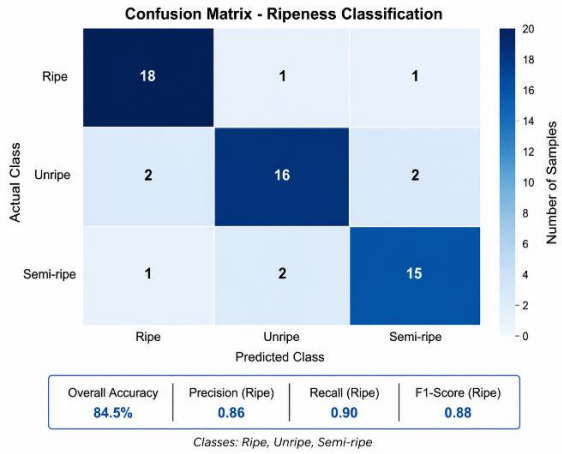
The system successfully detects fruits using contour-based detection after applying HSV masking. Each fruit is identified as a separate contour and enclosed within a bounding box.

TABLE 4:FRUIT DETECTION RESULTS

IMAGE	ACTUAL FRUITS	DETECTED FRUITS	ACCURACY
IMAGE 1	1	1	100%
IMAGE 2	2	2	100%
IMAGE 3	3	2	~66%
IMAGE 4	1	1	100%

The results show that detection accuracy is high in images with clear backgrounds and good lighting, while slight errors may occur in complex scenes.

6.3 Confusion Matrix Analysis



The confusion matrix shows the performance of the ripeness classification system for Ripe, Unripe, and Semi-ripe fruits. Most values lie on the diagonal, indicating correct predictions, with only a few misclassifications due to similar color features. The system achieves an overall accuracy of about 84.5%, demonstrating good effectiveness of the color-based approach.

6.4 Ripeness Classification Results

Ripeness is classified based on color percentage analysis using rule-based logic. The system categorizes fruits into:

- Ripe
- Unripe
- Semi-ripe

Table: Ripeness Classification Results

Fruit	Red %	Green %	Yellow %	Predicted Class
Apple 1	75%	10%	15%	Ripe
Apple 2	20%	65%	15%	Unripe
Apple 3	40%	30%	30%	Semi-ripe

The classification is effective when color distribution is distinct.

6.5 UI(STREAMLIT)INPUT/ OUTPUT SCREENS

The system includes a Streamlit-based user interface that allows users to upload images and view results interactively.

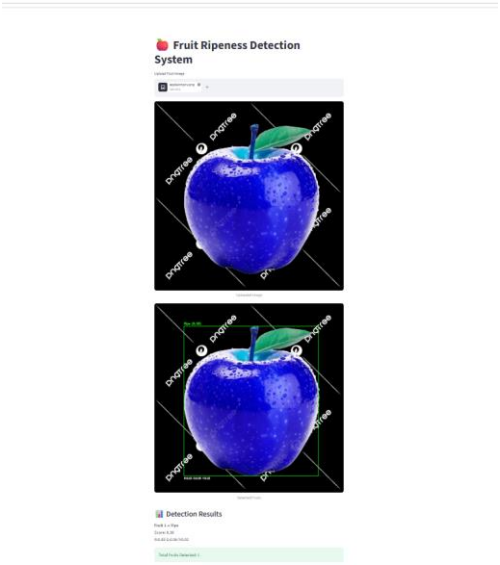
The UI displays:

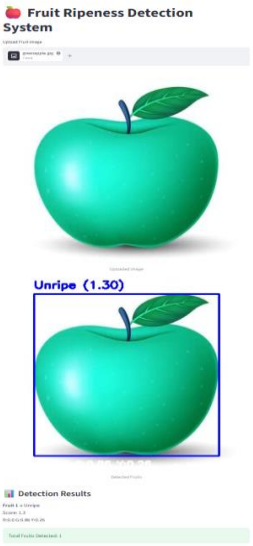
- Uploaded image
- Processed output
- Number of fruits detected
- Ripeness classification
- Color percentage details

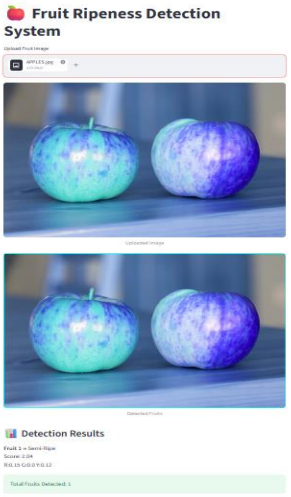
This enhances usability and makes the system suitable for real-time demonstration.

INPUT APPLE IMAGES

OUTPUT







7. DISCUSSION

1 Color-Based Detection Performance:

The HSV-based detection approach effectively segments fruit regions by isolating dominant colors such as red, green, and yellow. This method performs well in controlled environments and provides reliable fruit localization without requiring complex models.

2. Ripeness Classification Effectiveness:

The colour ratio–based ripeness scoring system demonstrates good accuracy in distinguishing between ripe, unripe, and semi-ripe fruits. The rule-based approach is simple, interpretable, and suitable for real-time applications.

3. Contour-Based Detection Limitations:

While contour detection successfully identifies individual fruits, it may struggle in cases of overlapping fruits or noisy backgrounds. Small artifacts may also be detected as false positives if not properly filtered.

4. Impact of Preprocessing:

Preprocessing steps such as Gaussian blur and HSV conversion significantly improve segmentation quality. Noise reduction and color enhancement help in achieving more accurate masking and contour detection.

5. Sensitivity to Lighting Conditions:

The system performance is influenced by lighting variations. Changes in illumination can affect HSV values, leading to minor inaccuracies in color detection and ripeness classification.

6. Real-Time Performance and Efficiency:

The system is lightweight and runs efficiently on standard CPUs without requiring GPU support. Since it avoids machine learning training, it achieves faster execution suitable for real-time applications.

8. CONCLUSION AND FUTURE WORK

This project presents a Fruit Detection and Ripeness Analysis system using HSV color space, color thresholding, contour detection, and colour ratio analysis. The system successfully detects fruits, counts them, and classifies their ripeness as ripe, unripe, or semi-ripe.The approach is lightweight, does not require model training, and runs efficiently on standard CPU systems. The integration of a Streamlit interface allows easy image upload and real-time visualization of results.

Key Contributions:

- Preprocessing pipeline using resizing, Gaussian blur, and HSV conversion.
- Color-based segmentation for detecting fruit regions.
- Contour detection for fruit identification and counting.
- Colour ratio–based ripeness classification.
- Simple and efficient system without GPU requirement.

Future Work:

- Improve accuracy under varying lighting conditions.
- Use deep learning models for better classification.
- Support multiple fruit types.
- Extend to real-time video processing.
- Deploy as mobile/web application.
